

DECENTRALIZED CONSENSUS ALGORITHM WITH DELAYED AND STOCHASTIC GRADIENTS*

BENJAMIN SIRB[†] AND XIAOJING YE[†]

Abstract. We analyze the convergence of a decentralized consensus algorithm with delayed gradient information across the network. The nodes in the network privately hold parts of the objective function and collaboratively solve for the consensus optimal solution of the total objective while they can only communicate with their immediate neighbors. In real-world networks, it is often difficult and sometimes impossible to synchronize the nodes, and therefore they have to use stale gradient information during computations. We show that, as long as the random delays are bounded in expectation and a proper diminishing step size policy is employed, the iterates generated by the decentralized gradient descent method converge to a consensual optimal solution. Convergence rates of both objective and consensus are derived. Numerical results on a number of synthetic problems and real-world seismic tomography datasets in decentralized sensor networks are presented to show the performance of the method.

Key words. decentralized consensus, delayed gradient, stochastic gradient, decentralized networks

1. Introduction. In this paper, we consider a decentralized consensus optimization problem arising from emerging technologies such as distributed machine learning [3, 10, 16, 19], sensor networks [13, 30, 36], and smart grids [11, 21]. Let $\mathcal{G} = (\mathcal{V}, \mathcal{E})$ be a network (undirected graph), where $\mathcal{V} = \{1, 2, \dots, m\}$ is the node (also called agent, processor, or sensor) set and $\mathcal{E} \subset \mathcal{V} \times \mathcal{V}$ is the edge set. Two nodes i and j are called neighbors if $(i, j) \in \mathcal{E}$. The communications between neighbor nodes are bidirectional, meaning that i and j can communicate with each other as long as $(i, j) \in \mathcal{E}$.

In a decentralized sensor network \mathcal{G} , individual nodes can acquire, store, and process data about large-sized objects. Each node i collects data and holds objective function $F_i(x; \xi_i)$ privately, where $\xi_i \in \Theta$ is random with fixed but unknown probability distribution in domain Θ to model environmental fluctuations such as noise in data acquisition and/or inaccurate estimation of objective function or its gradient. Here $x \in X$ is the unknown (e.g., the seismic image) to be solved, where the domain $X \subset \mathbb{R}^n$ is compact and convex. Furthermore, we assume that $F_i(\cdot; \xi_i)$ is convex for all $\xi_i \in \Theta$ and $i \in \mathcal{V}$, and we define $f_i(x) = \mathbb{E}_{\xi_i}[F_i(x; \xi_i)]$ which is thus convex with respect to $x \in X$. The goal of decentralized consensus optimization is to solve the minimization problem

$$(1) \quad \underset{x \in X}{\text{minimize}} \ f(x), \quad \text{where } f(x) := \sum_{i=1}^m f_i(x),$$

with the restrictions that $F_i(x; \xi_i)$, and hence $f_i(x)$, are accessible by node i only and that nodes i and j can communicate only if $(i, j) \in \mathcal{E}$ during the entire computation.

There are a number of practical issues that need to be taken into consideration in solving the real-world decentralized consensus optimization problem (1).

- The partial objective F_i (and f_i) is held privately by node i , and transferring F_i to a data fusion center is either infeasible or cost-ineffective due to data privacy, the large size of F_i , and/or limited bandwidth and communication power overhead of sensors. Therefore the nodes can only communicate their own estimates of $x \in \mathbb{R}^n$ with their neighbors in each iteration of a decentralized consensus algorithm.
- Since it is often difficult and sometimes impossible for the nodes to be fully synchronized, they may not have access to the most up-to-date (stochastic) gradient information during computations. In this case, the node i has to use out-of-date (stochastic) gradient $\nabla F_i(x_i(t - \tau_i(t)); \xi_i(t - \tau_i(t)))$, where $x_i(t)$ is the estimate of x obtained by node i at iteration t , and $\tau_i(t)$ is the level of (possibly random) delay of the gradient information at t .
- The estimates $\{x_i(t)\}$ by the nodes should tend to be consensual as t increases, and the consensual value is a solution of problem (1). In this case, there is a guarantee of retrieving a good estimate of x from any surviving node in the network even if some nodes are sabotaged, lost, or run out of power during the computation process.

In this paper, we analyze a decentralized consensus algorithm which takes all the factors above into consideration in solving (1). We provide comprehensive convergence analysis of the algorithm, including the decay rates of objective function and disagreements between nodes, in terms of iteration number, level of delays, and network structure, etc.

1.1. Related work. Distributed computing on networks is an emerging technology with extensive applications in modern machine learning [10, 16, 19], sensor networks [13, 30, 49, 50], and big data analysis [4, 31]. There are two types of scenarios in distributed computing: centralized and decentralized. In the centralized scenario, computations are carried out locally by worker (slave) nodes while computations of certain global variables must eventually be processed by designated master node or at a center of shared memory during each (outer) iteration. A major effort in this scenario has been devoted to update the global variable more effectively using an asynchronous setting in, for example, distributed centralized alternating direction method of multipliers (ADMM) [7, 5, 20, 42, 47]. In the decentralized scenario considered in this paper, the nodes privately hold parts of objective functions and can only communicate with neighbor nodes during computations. In many real-world applications, decentralized computing is particularly useful when a master-worker network setting is either infeasible or not economical, or the data acquisition and computation have to be carried out by individual nodes which then need to collaboratively solve the optimization problem. Decentralized networks are also more robust to node failure and can better address privacy concerns. For more discussions about motivations and advantages of decentralized computing, see, e.g., [15, 27, 29, 34, 38, 40] and references therein.

Decentralized consensus algorithms take the data distribution and communication restriction into consideration, so that they can be implemented at individual nodes in the network. In the *ideal synchronous case* of decentralized consensus where all the nodes are coordinated to finish computation and then start to exchange information with neighbors in each iteration, a number of developments have been made. A class of methods is to rewrite the consensus constraints for minimization problem (1)

by introducing auxiliary variables between neighbor nodes (i.e., edges), and apply ADMM (possibly with linearization or preconditioning techniques) to derive an implementable decentralized consensus algorithm [6, 12, 14, 23, 35, 46]. Most of these methods require each node to solve a local optimization problem every iteration before communication, and reach a convergence rate of $O(1/T)$ in terms of outer iteration (communication) number T for general convex objective functions $\{f_i\}$. First-order methods based on decentralized gradient descent require less computational cost at individual nodes such that between two communications they only perform one step of a gradient descent-type update at the weighted average of previous iterates obtained from neighbors. In particular, Nesterov's optimal gradient scheme is employed in decentralized gradient descent with diminishing step sizes to achieve rate of $O(1/T)$ in [15], where an alternative gradient method that requires excessive communications in each inner iteration is also developed and can reach a theoretical convergence rate of $O(\log T/T^2)$, despite that it seems to work less efficiently in terms of communications than the former in practice. A correction technique is developed for decentralized gradient descent with convergence rate as $O(1/T)$ with constant step size in [34], which results in a saddle-point algorithm, as pointed out in [24]. In [50], the authors combine Nesterov's gradient scheme and a multiplier-type auxiliary variable to obtain a fast optimality convergence rate of $O(1/T^2)$. Other first-order decentralized methods have also been developed recently, such as dual averaging [8]. Additional constraints for primal variables in decentralized consensus optimization (1) are considered in [45].

In real-world decentralized computing, it is often difficult and sometimes impossible to coordinate all the nodes in the network such that their computation and communication are perfectly synchronized. One practical approach for such *asynchronous consensus* is using a broadcast scenario where in each (outer) iteration, one node in the network is assumed to wake up at random and broadcasts its value to neighbors (but does not hear them back). A number of algorithms for broadcast consensus are developed, for instance, in [2, 13, 25, 26]. In particular, [26] develops a consensus optimization algorithm for (1) in the setting where every iteration one node in the network broadcasts its value to the neighbors, but there are no delays in (sub)gradients during their updates. Another important issue in the asynchronous setting is that nodes may have to use out-of-date (stale) gradient information during updates [27, 43]. This delayed scenario in gradient descent is considered in a distributed but not decentralized setting in [1, 18, 37, 48]. In addition, analysis of stochastic gradient in distributed computing is also carried out in [1, 33]. In [9], linear convergence rate of optimality is derived for strongly convex objective functions with delays. Extending [1], a *fixed* delay at all nodes is considered in dual averaging [17] and gradient descent [41] in a decentralized setting, but they did not consider more practical and useful *random* delays, and there are no convergence rates on node consensus provided in these papers. In [43], both random delays in communications and gradients are considered; however, no convergence rate is established in such a setting.

1.2. Contributions.

The contribution of this paper is in three phases. First, we consider a general decentralized consensus algorithm with randomly delayed and stochastic gradient (section 2). In this case, the nodes do not need to be synchronized and they may only have access to stale gradient information. This renders stochastic gradients with random delays at different nodes in their gradient updates, which is suitable for many real-world decentralized computing applications.

Second, we provide a comprehensive convergence analysis of the proposed algorithm (section 3). More precisely, we derive convergence rates for both the objective

function (optimality) and disagreement (feasibility constraint of consensus) and show their dependency on the characteristics of the problem, such as Lipschitz constants of (stochastic) gradients and spectral gaps of the underlying network.

Third, we conduct a number of numerical experiments on synthetic and real datasets to validate the performance of the proposed algorithm (section 4). In particular, we examine the convergence on synthetic decentralized least squares, robust least squares, and logistic regression problems. We also present the numerical results on the reconstruction of several seismic images in decentralized wireless sensor networks.

1.3. Notations and assumptions. In this paper, all vectors are column vectors unless otherwise noted. We denote by $x_i(t) \in \mathbb{R}^n$, the estimate of node i at iteration t , and $x(t) = (x_1(t), \dots, x_m(t))^T \in \mathbb{R}^{m \times n}$. We denote $\|x\| \equiv \|x\|_2$ if x is a vector and $\|x\| \equiv \|x\|_F$ if x is a matrix, which should be clear by the context. For any two vectors of the same dimension, $\langle x, y \rangle$ denotes their inner product, and $\langle x, y \rangle_Q := \langle x, Qy \rangle$ for symmetric positive semidefinite matrix Q . For notation simplicity, we use $\langle x, y \rangle = \sum_{i=1}^m \langle x_i, y_i \rangle$, where, x_i and y_i are the i th row of the $m \times n$ matrices x and y , respectively. Such matrix inner product is also generalized to $\langle x, y \rangle_Q$ for matrices x and y . In this paper, we set the domain $X := \{x \in \mathbb{R}^n : \|x\|_\infty \leq R\}$ for some $R > 0$, which can be thought of as the maximum pixel intensity in reconstructed images for instance. We further denote $\mathcal{X} := X^m \subset \mathbb{R}^{m \times n}$.

For each node i , we define $f_i(x) := \mathbb{E}_{\xi_i}[F_i(x; \xi_i)]$ as the expectation of objective function, and $g_i(t) := \nabla F_i(x(t); \xi_i(t))$ (here the gradient ∇ is taken with respect to x) is the stochastic gradient at $x_i(t)$ at node i . We let $\tau_i(t)$ be the delay of gradient at node i in iteration t , and $\tau(t) = (\tau_1(t), \dots, \tau_m(t))^T$. We write $f(x(t))$ in short for $\sum_{i=1}^m f_i(x_i(t)) \in \mathbb{R}$, $x(t - \tau(t))$ for $(x_1(t - \tau_1(t)), \dots, x_m(t - \tau_m(t)))^T \in \mathbb{R}^{m \times n}$, and $g(t - \tau(t))$ for $(g_1(t - \tau_1(t)), \dots, g_m(t - \tau_m(t)))^T \in \mathbb{R}^{m \times n}$. We assume f_i is continuously differentiable, ∇f_i has Lipschitz constant L_i , and denote $L := \max_{1 \leq i \leq m} L_i$.

Let $x^* \in \mathbb{R}^n$ be a solution of (1). We denote $\mathbf{1}(x^*)^T$ simply by x^* in this paper, which is clear by the context; for instance $f(x^*) = f(\mathbf{1}(x^*)^T) = \sum_{i=1}^m f_i(x^*)$. Furthermore, we let $y(T) := (1/T) \sum_{t=1}^T x(t+1)$ be the running average of $\{x(t+1) : 1 \leq t \leq T\}$ and $z(T) := (1/m) \sum_{i=1}^m y(T)$ be the consensus average of $y(T)$. We denote $J = (1/m)\mathbf{1}\mathbf{1}^T$, then $z(T) = Jy(T)$. Note that for all T , $z(T)$ is always consensual, but $x(T)$ and $y(T)$ may not be.

An important ingredient in decentralized gradient descent is the mixing matrix $W = [w_{ij}]$ in (2). For the algorithm to be implementable in practice, $w_{ij} > 0$ if and only if $(i, j) \in \mathcal{E}$. In this paper, we assume that W is symmetric and $\sum_{j=1}^m w_{ij} = 1$ for all i ; hence W is doubly stochastic, namely $W\mathbf{1} = \mathbf{1}$ and $\mathbf{1}^T W = \mathbf{1}^T$, where $\mathbf{1} = (1, \dots, 1)^T \in \mathbb{R}^m$. With the assumption that the network \mathcal{G} is simple and connected, we know $\|W\|_2 = 1$ and eigenvalue 1 of W has multiplicity 1 by the Perron–Frobenius theorem [22]. As a consequence, $Wx = x$ if and only if x is consensual, i.e., $x = c\mathbf{1}$ for some $c \in \mathbb{R}$. We further assume $W \succeq 0$ (otherwise use $\frac{1}{2}(I + W) \succeq 0$ since stochastic matrix W has spectral radius 1). Given a network \mathcal{G} , there are different ways to design the mixing matrix W . For some optimal choices of W , see, e.g., [32, 44].

Now we make several assumptions that are necessary in our convergence analysis.

1. The network $\mathcal{G} = (\mathcal{V}, \mathcal{E})$ is undirected, simple, and connected.
2. For all i and x , the stochastic gradient is unbiased, i.e., $\mathbb{E}_{\xi_i}[\nabla F_i(x; \xi_i)] = \nabla f_i(x)$ and $\mathbb{E}_{\xi_i}[\|\nabla F_i(x; \xi_i) - \nabla f_i(x)\|^2] \leq \sigma^2$ for some $\sigma > 0$.
3. The delays $\tau_i(t)$ may follow different distributions at different nodes, but their second moments are assumed to be uniformly bounded; i.e., there exists $B > 0$ such that $\mathbb{E}[\tau_i(t)^2] \leq B^2$ for all $i = 1, \dots, m$ and iteration t .

Since the domain X is compact and ∇f_i are all Lipschitz continuous, we know that $\|\nabla f_i\|$ is uniformly bounded. Furthermore, $\mathbb{E}[\|\nabla F_i(\cdot, \xi_i)\|] \leq \mathbb{E}[\|\nabla F_i(\cdot, \xi_i) - \nabla f_i(\cdot)\|] + \|\nabla f_i(\cdot)\| \leq \sigma + \|\nabla f_i(\cdot)\|$, we know that $\mathbb{E}[\|\nabla F_i(\cdot, \xi_i)\|]$ is also uniformly bounded. Therefore we denote by $G > 0$ the uniform bound such that $\|\nabla f_i\|, \mathbb{E}[\|\nabla F_i(\cdot, \xi_i)\|] \leq G$ for all i . We also assume that the random delay $\tau_i(t)$ and error of inexact gradient $\epsilon_i(t) := g_i(t) - \nabla f_i(x(t))$ are independent.

2. Algorithm. Taking the delayed stochastic gradient and the constraint that nodes can only communicate with immediate neighbors, we propose the following decentralized delayed stochastic gradient descent method for solving (1). Starting from an initial guess $\{x_i(0) : i = 1, \dots, m\}$, each node i performs the following updates iteratively:

$$(2) \quad x_i(t+1) = \Pi_X \left[\sum_{j=1}^m w_{ij} x_j(t) - \alpha(t) g_i(t - \tau_i(t)) \right].$$

Namely, in each iteration t , the nodes exchange their most recent $x_i(t)$ with their neighbors. Then each node takes weighted average of the received local copies using weights w_{ij} and performs a gradient descent-type update using a stochastic gradient $g_i(t - \tau_i(t))$ with delay $\tau_i(t)$ and step size $\alpha(t)$, and projects the result onto X . In addition, each node i tracks its own running average $y_i(t) = (1/t) \cdot \sum_{s=1}^t x_i(s+1)$ by simply updating $y_i(t) = (1 - 1/t) \cdot y_i(t-1) + (1/t) \cdot x_i(t+1)$ in iteration t .

Following the matrix notation in section 1.3, the iteration (2) can be written as

$$(3) \quad x(t+1) = \Pi_{\mathcal{X}} [Wx(t) - \alpha(t)g(t - \tau(t))].$$

Here the projection $\Pi_{\mathcal{X}}$ is accomplished by each node projecting to X due to the definition of X in section 1.3, which does not require any coordination between nodes. Note that the update (3) is also equivalent to

$$(4) \quad x(t+1) = \operatorname{argmin}_{x \in \mathcal{X}} \left\{ \langle g(t - \tau(t)), x \rangle + \frac{1}{2\alpha(t)} \|x - Wx(t)\|^2 \right\}.$$

In this paper, we may refer to the proposed decentralized delayed stochastic gradient descent algorithm by any of (2), (3), and (4) since they are equivalent.

3. Convergence analysis. In this section, we provide a comprehensive convergence analysis of the proposed algorithm (4) by employing a proper step size policy. In particular, we derive convergence rates for both the disagreement (Theorem 3.3) and objective function values (Theorem 3.8).

LEMMA 3.1. *For any $x \in \mathbb{R}^{m \times n}$, its projection onto \mathcal{X} yields nonincreasing disagreement. That is,*

$$(5) \quad \|(I - J)\Pi_{\mathcal{X}}(x)\| \leq \|(I - J)x\|.$$

Proof. See Appendix A. □

LEMMA 3.2. *Let $c_1 \geq 0$ and $c_2 > 0$, and define $\alpha(t) = 1/(c_1 + c_2\sqrt{t})$. Then for any $\lambda \in (0, 1)$ there is*

$$(6) \quad \sum_{s=0}^{t-1} \alpha(s) \lambda^{t-s-1} \leq \frac{\sqrt{\pi} \lambda^{-2}}{c_2 \sqrt{t} \log(\lambda^{-1})} = O\left(\frac{1}{\sqrt{t}}\right)$$

for all $t = 1, 2, \dots$

Proof. See Appendix B. □

Now we are ready to prove the convergence rate of disagreement in $x(t)$ and $y(t)$. In particular, we show that $(\sum_{i=1}^m \|x_i(t) - \bar{x}(t)\|^2)^{1/2}$ decays at the rate of $O(1/\sqrt{t})$, where $\bar{x}(t) = (1/m) \sum_{i=1}^m x_i(t)$. The same convergence rate holds for the disagreement of running average $y(t)$. More specifically, these convergence rates are given by the bounds in the following theorem.

THEOREM 3.3. *Let $\{x(t)\}$ be the iterates generated by Algorithm (4) with $\alpha(t) = [2(L + \eta\sqrt{t})]^{-1}$ for some $\eta > 0$, and $\lambda = \|W - J\|$. Then λ is the second largest eigenvalue of W and hence $\lambda \in (0, 1)$. Moreover, the disagreement of $x(t)$ is bounded by*

$$(7) \quad \mathbb{E}[\|(I - J)x(t)\|] \leq \sqrt{m}G \sum_{s=0}^{t-1} \alpha(s)\lambda^{t-s-1} \leq \frac{\sqrt{\pi m}G\lambda^{-2}}{\eta\sqrt{t}\log(\lambda^{-1})} = O\left(\frac{1}{\sqrt{t}}\right),$$

and the disagreement of running average $y(T) = (1/m) \sum_{t=1}^T x(t+1)$ is bounded by

$$(8) \quad \mathbb{E}[\|(I - J)y(T)\|] \leq \frac{2\sqrt{\pi m}G\lambda^{-2}}{\eta\sqrt{T}\log(\lambda^{-1})} = O\left(\frac{1}{\sqrt{T}}\right).$$

Proof. We first prove the bound on disagreement between $\{x_i(t) : 1 \leq i \leq m\}$, i.e., (7), by induction. It is trivial to show that this bound holds for $t = 1$. Assuming (7) holds for t , we have

$$(9) \quad \begin{aligned} \mathbb{E}[\|(I - J)x(t+1)\|] &= \mathbb{E}[\|(I - J)\Pi_{\mathcal{X}}(Wx(t) - \alpha(t)g(t - \tau(t)))\|] \\ &\leq \mathbb{E}[\|(I - J)(Wx(t) - \alpha(t)g(t - \tau(t)))\|] \\ &\leq \mathbb{E}[\|(I - J)Wx(t)\|] + \alpha(t)\mathbb{E}[\|(I - J)g(t - \tau(t))\|] \\ &\leq \mathbb{E}[\|(I - J)Wx(t)\|] + \alpha(t)\sqrt{m}G, \end{aligned}$$

where we used Lemma 3.1 in the first inequality, and $\|I - J\| \leq 1$ and $\mathbb{E}[\|g_i(t - \tau_i(t))\|] \leq G$ in the last inequality. Noting that $J^2 = J$ and $JW = WJ = J$, we have

$$(W - J)(I - J) = (I - J)W.$$

Therefore we obtain

$$(10) \quad \begin{aligned} \mathbb{E}[\|(I - J)x(t+1)\|] &\leq \mathbb{E}[\|(I - J)Wx(t)\|] + \alpha(t)\sqrt{m}G \\ &= \mathbb{E}[\|(W - J)(I - J)x(t)\|] + \alpha(t)\sqrt{m}G \\ &\leq \mathbb{E}[\|(W - J)\| \|(I - J)x(t)\|] + \alpha(t)\sqrt{m}G \\ &\leq \lambda\sqrt{m}G \sum_{s=0}^{t-1} \alpha(s)\lambda^{t-s-1} + \alpha(t)\sqrt{m}G \\ &= \sqrt{m}G \sum_{s=0}^t \alpha(s)\lambda^{t-s}, \end{aligned}$$

where we used the induction assumption for t in the last inequality. Applying Lemma 3.2 to the bound yields the second inequality in (7), which shows that $\mathbb{E}[\|(I - J)x(t)\|]$ decays at the rate of $O(1/\sqrt{t})$.

By convexity of $\|\cdot\|$ and definition of $y(T)$, we obtain that

$$(11) \quad \mathbb{E}[\|(I - J)y(T)\|] \leq \frac{1}{T} \sum_{t=1}^T \mathbb{E}[\|(I - J)x(t+1)\|] \leq \frac{2\sqrt{\pi m}G\lambda^{-2}}{\eta\sqrt{T}\log(\lambda^{-1})}$$

by applying (7) and using $\sum_{t=1}^T \frac{1}{\sqrt{t}} \leq 2\sqrt{T}$. Therefore the disagreement $\mathbb{E}[\|(I - J)y(T)\|]$ also decays at the rate of $O(1/\sqrt{T})$. \square

The convergence rate of disagreement also yields an estimate of differences between consecutive iterates $x(t)$ and $x(t+1)$, which is given by the following corollary.

COROLLARY 3.4. *Let $\{x(t)\}$ be the iterates generated by Algorithm (4) with the settings of $\alpha(t)$, λ , and η same as in Theorem 3.3. Then there is*

$$(12) \quad \mathbb{E}[\|x(t+1) - x(t)\|] \leq \frac{C}{\sqrt{t}},$$

where $C := \frac{\sqrt{m}G}{\eta} [\frac{\sqrt{\pi}\lambda^{-2}}{\log(\lambda^{-1})} + \frac{1}{2}]$ is a constant independent of t .

Proof. See Appendix C. \square

From the estimate of difference between consecutive iterates, we can also bound the expected difference between $x(t)$ and $x(t - \tau(t))$ as follows.

COROLLARY 3.5. *Let $\{x(t)\}$ be the iterates generated by Algorithm (4) with the settings of $\alpha(t)$, λ , and η same as in Theorem 3.3. Then there is*

$$(13) \quad \mathbb{E}[\|x(t) - x(t - \tau(t))\|] \leq C \left(\frac{\sqrt{2m}B}{\sqrt{t}} + \frac{4mB^2}{t} \right) = O\left(\frac{1}{\sqrt{t}}\right),$$

where C is the constant defined in Corollary 3.4. In particular, if $t \geq 8mB^2$, there is $\mathbb{E}[\|x(t) - x(t - \tau(t))\|] \leq \frac{2\sqrt{2m}CB}{\sqrt{t}}$.

Proof. See Appendix D. \square

Without loss of generality and for sake of notation simplicity, we assume iteration number $t > 8mB^2$ and $\mathbb{E}[\|x(t) - x(t - \tau(t))\|] \leq \frac{2\sqrt{2m}CB}{\sqrt{t}}$ in the remaining derivations. The decay rate $O(1/\sqrt{t})$ of $\mathbb{E}[\|x(t) - x(t - \tau(t))\|]$ is useful to estimate the convergence rate of objective function value later.

LEMMA 3.6. *Let $\{x(t)\}$ be the iterates generated by Algorithm (3); then the following inequality holds for all $T \geq 1$:*

$$(14) \quad \sum_{t=1}^T \mathbb{E} \langle \nabla f(x(t)) - \nabla f(x(t - \tau(t))), x(t+1) - x^* \rangle \leq 8\sqrt{2nLTmRCB},$$

where C is the constant defined in Corollary 3.4.

Proof. See Appendix E. \square

Now we are ready to prove the convergence rate of objective function value. We first present the estimate of this rate for running averages $y(t)$ in the following theorem.

THEOREM 3.7. *Let $\{x(t)\}$ be the iterates generated by Algorithm (3) with $\alpha(t) = [2(L + \eta\sqrt{t})]^{-1}$ for some $\eta > 0$; then*

$$(15) \quad \mathbb{E}[f(y(T))] - f(x^*) \leq \frac{LD_{\mathcal{X}}^2}{T} + \frac{K}{\sqrt{T}} = O\left(\frac{1}{\sqrt{T}}\right),$$

where $y(T) = (1/T) \sum_{t=1}^T x(t+1)$ is the running average of $\{x(t)\}$, $\mathcal{D}_{\mathcal{X}} = 2\sqrt{mn}R$ is the diameter of \mathcal{X} , and $K := \eta\mathcal{D}_{\mathcal{X}}^2 + 4\sqrt{2mLD_{\mathcal{X}}CB} + (4m\sigma^2/\eta)$.

Proof. See Appendix F. \square

We have shown that the running average $y(T)$ makes the objective function decay as in (15). However, since each node i obtains its own $y_i(T)$ which may not be consensual (and the left-hand side of (15) could be negative), we need to look at their consensus average $z(T) = (1/m) \sum_{i=1}^m y_i(T)$ and the convergence rate of its objective function value. This is given in the following theorem.

THEOREM 3.8. *Let $x(t)$ be generated by Algorithm (2) with $\alpha(t) = [2(L + \eta\sqrt{t})]^{-1}$ for some $\eta > 0$. Let $y(T) = (1/T) \sum_{t=1}^T x(t+1)$ be the running average of $x(t)$ and $z(T) = Jy(T) = (1/m) \sum_{i=1}^m y_i(T)$ be the consensus average of $y(T)$; then*

$$(16) \quad 0 \leq \mathbb{E}[f(z(T))] - f(x^*) \leq \frac{LD_{\mathcal{X}}^2 + 2\sqrt{m}LC^2}{T} + \frac{K + 2\sqrt{m}CG}{\sqrt{T}} = O\left(\frac{1}{\sqrt{T}}\right),$$

where C is defined as in Corollary 3.4, and $\mathcal{D}_{\mathcal{X}}$ and K are defined as in Theorem 3.7.

Proof. We first bound the difference between the function values at the running average $y(T)$ and the consensus average $z(T) = Jy(T)$:

$$(17) \quad \begin{aligned} f(y(T)) - f(z(T)) &= \sum_{i=1}^m (f_i(y_i(T)) - f_i(z(T))) \\ &\leq \sum_{i=1}^m \langle \nabla f_i(z(T)), y_i(T) - z(T) \rangle + \frac{L_i}{2} \|y_i(T) - z(T)\|^2 \\ &\leq \sqrt{m}G\|(I - J)y(T)\| + \frac{L}{2} \|(I - J)y(T)\|^2 \leq \frac{2\sqrt{m}CG}{\sqrt{T}} + \frac{2C^2L}{T}, \end{aligned}$$

where we used convexity of f_i and Lipschitz continuity of ∇f_i in the first inequality, $\|\nabla f_i\| \leq G$ and convexity of $\|\cdot\|^2$ in the second inequality, and Theorem 3.3 to get the last inequality. Therefore combining (17) and (15) from Theorem 3.7, we obtain the bound in (16). Note that $z(T)$ is consensus, so $f(z(T)) \geq f(x^*)$ since x^* is a consensus optimal solution of (1). This completes the proof. \square

In summary, we have shown that the running average $y_i(T)$, which can be easily updated by each node i , yields convergence in optimality and consensus feasibility. More precisely, Theorem 3.3 implies that $\|y_i(T) - z(T)\|$ converges to 0 at the rate of $O(1/\sqrt{T})$ for all nodes i , where $z(T) = (1/m) \sum_{i=1}^m y_i(T)$ is their consensus average, and Theorem 3.8 implies that $f(z(T))$ converges to $f(x^*)$ at the rate of $O(1/\sqrt{T})$. It is known that $O(1/\sqrt{T})$ is the optimal rate for stochastic gradient algorithms in centralized setting, and hence these two Theorems suggest an encouraging fact that such rate can be retained even if the problem becomes much more complicated; i.e., the gradients are stochastic and delayed, and the computation is carried out in decentralized setting. To retain convergence in this complex setting, we employed a diminishing step size policy as commonly used in stochastic optimization. Such step size policy results in a convergence rate of $O(1/\sqrt{T})$ even without delays and randomness in gradients. Furthermore, due to errors and uncertainties in delayed and stochastic gradients, the iterates may be directed further apart from solution during computations. As a consequence, the constant in the estimated convergence rate appears to depend on the bound of set X rather than the distance between initial guess and solution set as in the setting with nondelayed and nonstochastic gradients.

4. Numerical experiments. In this section, we test algorithm (2) on decentralized consensus optimization problem (1) with delayed stochastic gradients using a number of synthetic and real datasets. The structure of network $\mathcal{G} = (\mathcal{V}, \mathcal{E})$ and objective function in (1) are explained for each dataset, followed by performance evaluation

shown in plots of objective function $f(z(T))$ and disagreement $\sum_{i=1}^m \|y_i(T) - z(T)\|^2$ versus the iteration number T , where $y_i(T) = (1/T) \sum_{t=1}^T x_i(t+1)$ is the running average of $x_i(t)$ in algorithm (2) at each node i , and $z(T) = (1/m) \sum_{i=1}^m y_i(T)$ is the consensus average at iteration T .

4.1. Test on synthetic data. We first test on three different types of objective functions using synthetic datasets. In particular, we apply algorithm (2) to decentralized least squares, decentralized robust least squares, and decentralized logistic regression problems with different delay and stochastic error combinations. Then we compare the performance of the algorithm with and without delays and stochastic errors in gradients. The performance of the algorithm on different network size m and time comparison with synchronous algorithm are also presented.

In the first set of tests on three different objective functions, we simulate a network of regular 5×5 two-dimensional (2D) lattice of size $m = 25$. We set dimension of unknown x to $n = 10$ and generate an $\hat{x} \in \mathbb{R}^n$ using MATLAB built-in function `rand`, and set the ℓ_∞ radius of X to $R = 1$. For each node i , we generate matrices $A_i \in \mathbb{R}^{p_i \times n}$ with $p_i = 5$ using `randn`, and normalize each column into unit ℓ_2 ball in \mathbb{R}^{p_i} for $i = 1, \dots, m$. Then we simulate $b_i = A_i \hat{x} + \epsilon_i$, where ϵ_i is generated by `randn` with mean 0 and standard deviation 0.001. For decentralized least squares problem, we set the objective function to $f_i(x) = (1/2) \|A_i x - b_i\|^2$ at node i . Therefore the Lipschitz constant of ∇f_i is $L_i = \|A_i^\top A_i\|_2$, and we further set $L = \max_{1 \leq i \leq m} \{L_i\}$. The initial guess $x_i(0)$ is set to 0 for all i . For each iteration t , the delay $\tau_i(t)$ at each node i is uniformly drawn from integers 1 to B with $B = 5, 10$, and 20. For given t , the stochastic gradient is simulated by setting $\nabla F_i(x_i(t); \xi_i(t)) = A_i^\top (A_i x_i(t) - b_i) + \xi_i(t)$, where $\xi_i(t)$ is generated by `randn` with mean 0 and standard deviation σ set to 0.01 and 0.05. We run our algorithm using step size $\alpha(t) = 1/(2L + 2\eta\sqrt{t})$ with $\eta = 0.01$. The objective function $f(z(T)) - f^*$ and disagreement $\sum_{i=1}^m \|y_i(T) - z(T)\|^2$ versus the iteration number T are plotted in the top row of Figure 1, where the reference optimal objective $f^* = \min_{x \in X} \sum_{i=1}^m f_i(x)$ is computed using centralized Nesterov's accelerated gradient method [28, 39]. In the two plots, we observe that both $f(z(T)) - f^*$ and disagreement $\sum_{i=1}^m \|y_i(T) - z(T)\|^2$ decays to 0 as justified by our theoretical analysis in section 3. In general, we observe that delays with larger bound B and/or larger standard deviation σ in stochastic gradient yield slower convergence, as expected.

We also tested on two different objective functions: robust least squares and logistic regression. In robust least squares, we apply (2) to the decentralized optimization problem (1), where the objective function is set to

$$(18) \quad f_i(x) := \sum_{j=1}^{p_i} h_i^j(x), \text{ where } h_i^j(x) = \begin{cases} \frac{1}{2} |(a_i^j)^\top x - b_i^j|^2 & \text{if } |(a_i^j)^\top x - b_i^j| \leq \delta, \\ \delta (|(a_i^j)^\top x - b_i^j| - \frac{\delta}{2}) & \text{if } |(a_i^j)^\top x - b_i^j| > \delta, \end{cases}$$

where $(a_i^j)^\top \in \mathbb{R}^n$ is the j th row of matrix $A_i \in \mathbb{R}^{p_i \times n}$ and $b_i^j \in \mathbb{R}$ is the j th component of $b_i \in \mathbb{R}^{p_i}$ at each node i . In this test, we simulate network $\mathcal{G} = (\mathcal{V}, \mathcal{E})$ and set A_i , b_i , m , n , R , and $x_i(0)$ the same way as in the decentralized least squares test above, and set the parameter of the Huber norm in the robust least squares $\delta = 0.05$. The stochastic gradient is given by $\nabla F_i(x; \xi_i(t)) = \sum_{j=1}^{p_i} \nabla h_i^j(x) + \xi_i(t)$, where $\xi_i(t)$ is generated as before with σ set to 0.01 and 0.05. Lipschitz constants L_i and L are determined as in the previous test. The settings of η and $\tau_i(t)$ remain the same as well. The objective function $f(z(T)) - f^*$ and disagreement $\sum_{i=1}^m \|y_i(T) - z(T)\|^2$ are plotted in the middle row of Figure 1. In these two plots, we observe similar

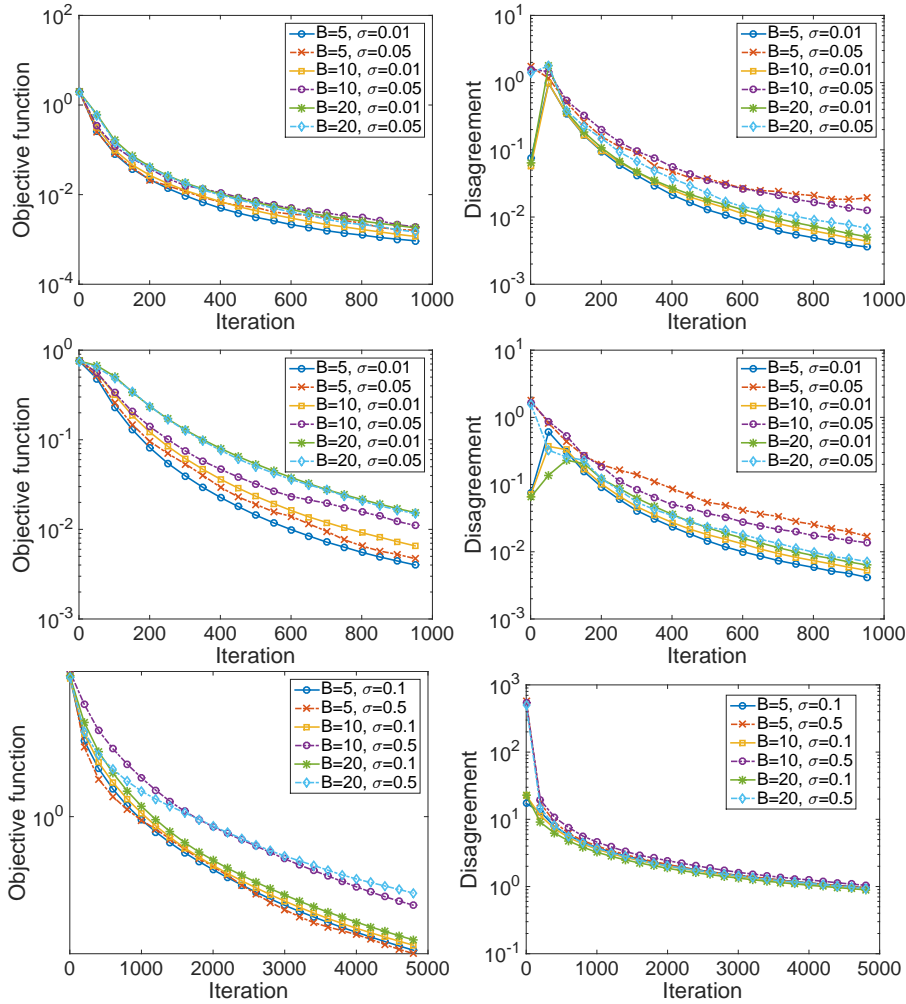

FIG. 1. Test on synthetic decentralized least-squares (top), robust least-squares (middle), and logistic regression (bottom) for different levels of delay B and standard deviation in stochastic gradient σ . Left: objective function $f(z(T)) - f^*$ versus iteration number T , where $f^* = f(x^*)$ is the optimal value. Right: disagreement $\sum_{i=1}^m \|y_i(T) - z(T)\|^2$ versus iteration number T .

convergence behavior as in the test on the decentralized least squares problem above. For the decentralized logistic regression, we generate \hat{x} , ϵ_i , and A_i the same way as before, and set $b_i = \text{sign}(A_i \hat{x} + \epsilon_i) \in \{\pm 1\}^{p_i}$ ($\text{sign}(0) := 1$). Now the objective function f_i at node i is set to

$$(19) \quad f_i(x) = \sum_{j=1}^{p_i} \left(\log[1 + \exp((a_i^j)^\top x)] - b_i^j (a_i^j)^\top x \right),$$

where $(a_i^j)^\top \in \mathbb{R}^n$ is the j th row of matrix $A_i \in \mathbb{R}^{p_i \times n}$ and $b_i^j \in \mathbb{R}$ is the j th component of $b_i \in \mathbb{R}^{p_i}$. Then we perform (2) to solve this problem in the network \mathcal{G} above. Since $\nabla^2 f_i(x) = \sum_j [\exp((a_i^j)^\top x) / (1 + \exp((a_i^j)^\top x))^2] \cdot a_i^j (a_i^j)^\top \leq (1/4) \cdot \sum_j a_i^j (a_i^j)^\top = (1/4) \cdot A_i^\top A_i$, there is $\|\nabla f_i(x) - \nabla f_i(x')\| \leq (1/4) \cdot \|A_i^\top A_i\| \|x - x'\|$ for all $x, x' \in \mathbb{R}^n$.

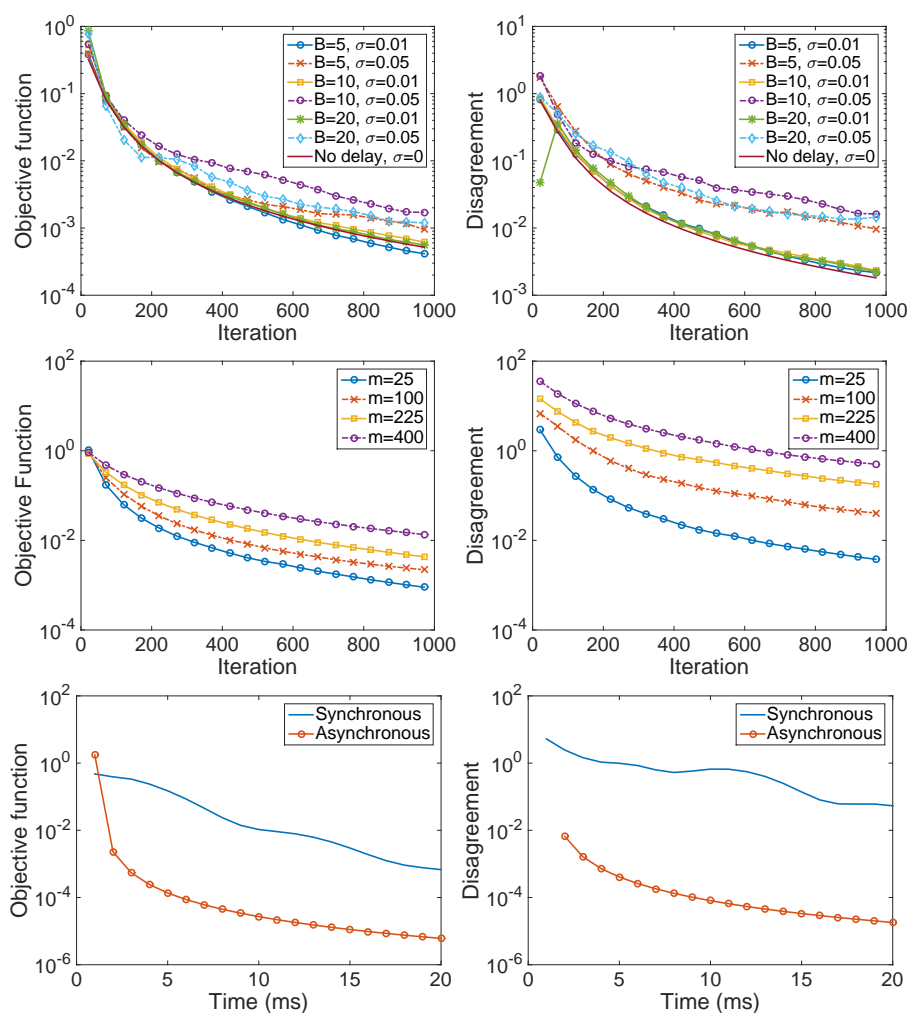

FIG. 2. Test on synthetic decentralized least-squares with and without delay/stochasticity (top) and varying network size (bottom). Left: objective function $f(z(T))$ versus iteration number T . Right: disagreement $\sum_{i=1}^m \|y_i(T) - z(T)\|^2$ versus iteration number T .

Therefore we set $L_i = \|A_i^\top A_i\|_2/4$. The settings of the delay $\tau_i(t)$, η , and initial value $x_i(0)$ remain the same as before. The stochastic error level σ is set to 0.1 and 0.5. The objective function $f(z(T)) - f^*$ and disagreement $\sum_{i=1}^m \|y_i(T) - z(T)\|^2$ are plotted in the bottom row of Figure 1, where similar convergence behavior as in the previous tests can be observed.

We also compared the performance of decentralized gradient descent method with and without delay and stochasticity in the gradients. In this test, we synthesized networks and data in the same way as in the decentralized least squares test above. In addition, we plotted the result of $\tau_i(t) = 0$ for all $i = 1, \dots, m$ and $\sigma = 0$ is for comparison. These results are shown in the top row of Figure 2, The objective function value (top left) and disagreement (top right) both decay slightly faster when there are no delay and stochastic error, as shown in Figure 2, which is within expectations. We further tested the performance when the network size varies. In this experiment, we used

FIG. 3. *Seismic tomography of an active volcano using wireless sensor network. When there is a seismic activity (e.g., an earthquake) happens underground, its acoustic waves (curved arrows) travel to the ground surface and are detected by the sensors (triangles). Then the sensors communicate wirelessly to reconstruct the entire image, where each square represents a pixel of the image $x \in \mathbb{R}^n$.*

four 2D lattice networks, with sizes $m = 5^2, 10^2, 15^2$, and 20^2 . The size of x and A_i at each node are the same as before. The objective function value (middle left) and disagreement (middle right) both decays, while it appears that network with smaller size decays faster, as shown in Figure 2. To demonstrate effectiveness of asynchronous consensus, we applied EXTRA [34], a state-of-the-arts synchronous decentralized consensus optimization method, to the same data generated in decentralized least squares problem with network size $m = 100$ and $\sigma = 0$ (no stochastic error in gradients). We draw computing times of these 100 nodes as independent random variables between $[.001, .500]$ ms every gradient evaluation. The synchronous algorithm EXTRA needs to wait for the slowest node to finish computation and then start a new iteration, whereas in the asynchronous algorithm (2) the nodes communicate with neighbors every 0.01 ms using updates obtained by delayed gradients. We plotted the objective function $f(z(T)) - f^*$ and disagreement $\sum_{i=1}^m \|y_i(T) - z(T)\|^2$ versus running time in the bottom row of Figure 2, which show that the asynchronous updates can be more time efficient by not waiting for the slowest node in each iteration.

4.2. Test on real data. We apply algorithm (2) to seismic tomography where the data is collected and then processed by the nodes (sensors) in a wireless sensor network. In brief, underground seismic activities (such as earthquakes) generate acoustic waves (we use P-wave here) which travel through the materials and are detected by the sensors placed on the ground. An explanatory picture of seismic tomography using a sensor network is shown in Figure 3. After data preprocessing, sensor i obtains a matrix $A_i \in \mathbb{R}^{p_i \times n}$ and a vector $b_i \in \mathbb{R}^{p_i}$ and hence an objective $f_i(x) = (1/2)\|A_i x - b_i\|^2$ for $i = 1, \dots, m$. Here $(A_i)_{kl}$, the (k, l) th entry of matrix A_i , is the distance that the wave generated by k th seismic activity travels through pixel l for $k = 1, \dots, p_i$ (p_i is the total number of seismic activities) and $l = 1, \dots, n$ (n is the total number of pixels in the image), and $(b_i)_k$, the k th component of b_i , is the total time that the wave travels from the source of k th seismic activity to the sensor i . Then x_l , the l th component of $x \in \mathbb{R}^n$, represents the unknown “slowness” (reciprocal of the velocity of the traveling wave) at that location (pixel) l . The sensors then collaboratively solve for the image x that minimizes the sum of their objective functions, under the constraint that only neighbor nodes may communicate during the computation process,

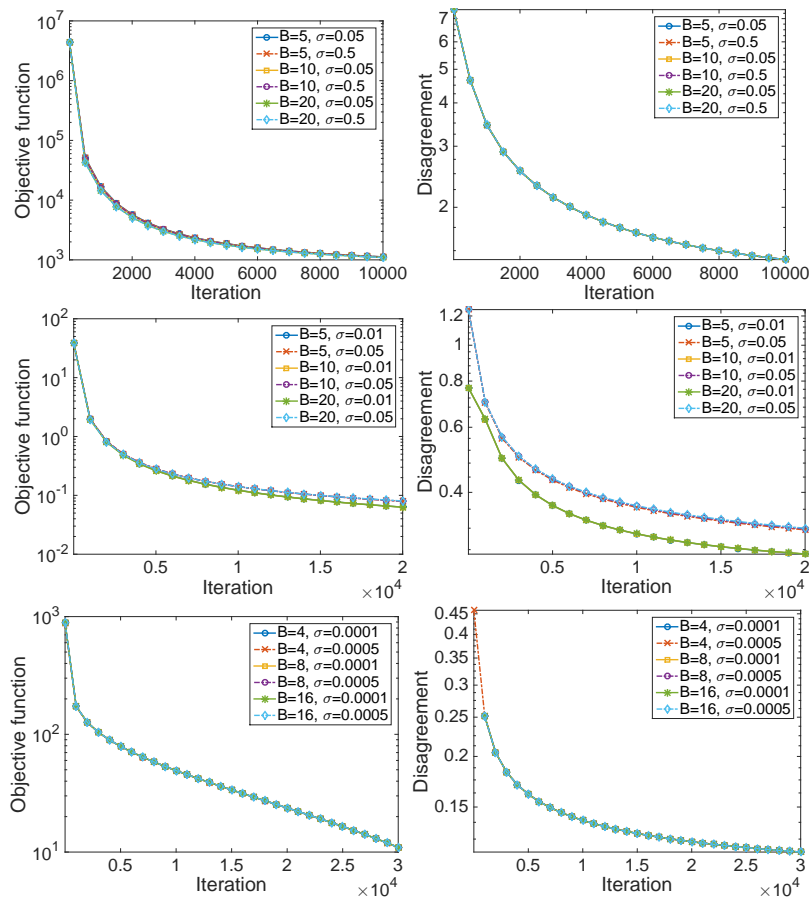

FIG. 4. Tests on real seismic image reconstruction problems with 2D image with $n = 64^2$ (top), 3D image with $n = 32^3$ (middle), and 3D image with $n = 160 \times 200 \times 24$ (bottom) for different levels of delay B and standard deviation in stochastic gradient σ . Left: objective function $f(z(T))$ versus iteration number T . Optimal value indicates $f^* := f(x^*)$. Right: disagreement $\sum_{i=1}^m \|y_i(T) - z(T)\|^2$ versus iteration number T .

since wireless signal transmission can only occur within a limited geographical range. Once x is reconstructed from $\min_x f(x) = \sum_{i=1}^m f_i(x)$, the material (e.g., rock, sand, oil, or magma) at each pixel l can be identified by the value of x_l .

The first dataset consists of a simple and connected network G with $m = 32$ nodes, where each node has three neighbors, and $A_i \in \mathbb{R}^{p_i \times n}$ and $b_i \in \mathbb{R}^{p_i}$, where the number of seismic events is $p_i = 512$ and the size of a 2D image x to be reconstructed is $n = 64^2 = 4096$. Since the matrix by stacking all A_i is still underdetermined, we employ an objective function with Tikhonov regularization as $f_i(x) = (1/2)(\|A_i x - b_i\|^2 + \mu \|x\|^2)$ at each node i , where μ is set to 0.1. Note that more adaptive regularizers of x , such as ℓ_1 and total variation (TV) which result in a nonsmooth objective function, will be explored in future research. We apply algorithm (3) with bound B of delays set to 5, 10, and 20 and standard deviation σ of stochastic gradient to 0.5 and 0.05. We run our algorithm using step size $\alpha(t) = 1/(2L + 2\eta\sqrt{t})$ with η that minimizes the constant of $1/\sqrt{T}$ term in Theorem 3.8. The objective function $f(z(T))$ and disagreement $\sum_{i=1}^m \|y_i(T) - z(T)\|^2$ versus the iteration number T are plotted in the top row of Figure 4, where convergence of both quantities can be observed.

FIG. 5. Cross section of a reconstructed 3D seismic image generated by a centralized LSQR solver (left) and decentralized algorithm with delayed stochastic gradient (2) with $B = 4$ and $\sigma = 10^{-4}$ (right).

The second seismic dataset contains a connected network G of size $m = 50$, where each node has three neighbors, and matrices $A_i \in \mathbb{R}^{p_i \times n}$ and $b_i \in \mathbb{R}^{p_i}$, where $p_i = 800$ and the size of three-dimensional (3D) image x to be reconstructed is $n = 32^3 = 32768$. We use the same objective function with Tikhonov regularization as before with $\mu = 0.01$. Other parameters are set the same as in the previous test on a 2D seismic image. The settings for B and σ remain the same. The objective function $f(z(T))$ and disagreement $\sum_{i=1}^m \|y_i(T) - z(T)\|^2$ versus the iteration number T are plotted in the middle row of Figure 4, where similar convergence behavior can be observed.

The last seismic dataset consists of a connected network G of size $m = 10$, where the average node degree is 5, and matrices $A_i \in \mathbb{R}^{p_i \times n}$ and $b_i \in \mathbb{R}^{p_i}$, where $p_i = 1,816$ and the size of 3D image x to be reconstructed is $n = 160 \times 200 \times 24 = 768,000$. In this test, we employ objective $f_i(x) = (1/2)(\|A_i x - b_i\|^2 + \mu \|Dx\|^2)$, where $\mu = 0.1$ and D is the discrete gradient operator. Other parameters are set the same as in the previous two seismic datasets. The bound B of delay is set to 4, 8, and 16, and standard deviation of stochastic gradient σ is set to $1e-4$ and $5e-4$. The objective function $f(z(T))$ and disagreement $\sum_{i=1}^m \|y_i(T) - z(T)\|^2$ versus the iteration number T are plotted in the last row of Figure 4. The reconstructed image is displayed in the right panel of Figure 5. By comparing with the solution obtained by centralized LSQR solver (left), we can see the image is faithfully reconstructed on a decentralized network with delayed stochastic gradients.

5. Concluding remarks. In this paper, we analyzed the convergence of decentralized delayed stochastic gradient descent method as in (2) for solving the consensus optimization (1). The algorithm takes into consideration that the nodes in the network privately hold parts of the objective function and collaboratively solve for the consensus optimal solution of the total objective while they can only communicate with their immediate neighbors, as well as the delays of gradient information in real-world networks where the nodes cannot be fully synchronized. We show that, as long as the random delays are bounded in expectation and a proper diminishing step size policy is employed, the iterates generated by the decentralized gradient decent method converge to a consensus solution. Convergence rates of both objective and

consensus were derived. Numerical results on a number of synthetic and real data were also presented for validation.

Appendix A. Proof of Lemma 3.1.

Proof. It suffices to show that for any fixed $R > 0$ and $X = \{x \in \mathbb{R}^m : \|x\|_\infty \leq R\}$, there is

$$(20) \quad \|(I - J)\Pi_X(x)\| \leq \|(I - J)x\|$$

for all $x \in \mathbb{R}^m$. Note that for $x = (x_1, x_2, \dots, x_m)^\top \in \mathbb{R}^m$, there is

$$\|(I - J)x\|^2 = \sum_{i=1}^m (x_i - \bar{x})^2,$$

where $\bar{x} := (1/m) \sum_{i=1}^m x_i$. We only need to show that if all $\{x_i : x_i < -R\}$ are projected to $-R$ then $\|(I - J)x\|^2$ will reduce. Without loss of generality, suppose $x_1, \dots, x_\ell < -R$ and $x_{\ell+1}, \dots, x_m \geq -R$, and denote the means of these two groups by

$$(21) \quad \mu_1 := \frac{1}{\ell} \sum_{i=1}^{\ell} x_i < -R \quad \text{and} \quad \mu_2 := \frac{1}{m - \ell} \sum_{i=\ell+1}^m x_i \geq -R.$$

Then we have $\bar{x} = (\ell\mu_1 + (m - \ell)\mu_2)/m$ and

$$(22) \quad \begin{aligned} & \|(I - J)x\|^2 \\ &= \sum_{i=1}^m (x_i - \bar{x})^2 = \sum_{i=1}^m \left(x_i - \frac{\ell\mu_1 + (m - \ell)\mu_2}{m} \right)^2 \\ &= \sum_{i=1}^{\ell} \left(x_i - \frac{\ell\mu_1 + (m - \ell)\mu_2}{m} \right)^2 + \sum_{i=\ell+1}^m \left(x_i - \frac{\ell\mu_1 + (m - \ell)\mu_2}{m} \right)^2 \\ &= \sum_{i=1}^{\ell} \left((x_i - \mu_1) + \frac{m - \ell}{m}(\mu_1 - \mu_2) \right)^2 + \sum_{i=\ell+1}^m \left((x_i - \mu_2) + \frac{\ell}{m}(\mu_2 - \mu_1) \right)^2 \\ &= \sum_{i=1}^{\ell} (x_i - \mu_1)^2 + 2\frac{m - \ell}{m}(\mu_1 - \mu_2) \sum_{i=1}^{\ell} (x_i - \mu_1) + \ell \left(\frac{m - \ell}{m} \right)^2 (\mu_1 - \mu_2)^2 \\ &\quad + \sum_{i=\ell+1}^m (x_i - \mu_2)^2 + 2\frac{\ell}{m}(\mu_2 - \mu_1) \sum_{i=\ell+1}^m (x_i - \mu_2) + (m - \ell) \left(\frac{\ell}{m} \right)^2 (\mu_2 - \mu_1)^2 \end{aligned}$$

After x_1, \dots, x_ℓ are projected to $-R$ (and $x_{\ell+1}, \dots, x_m$ remain unchanged), their mean is updated from μ_1 to $-R$ for all $i = 1, \dots, \ell$, and $\mu_2 - \mu_1 (\geq 0)$ reduces to $\mu_2 + R (\geq 0)$. Therefore the first, third, and sixth terms in the right-hand side of (22) are decreased, the second and fifth terms remain zero, and the fourth term remains unchanged. Thus, $\|(I - J)x\|$ reduces after projection to $[-R, \infty)^m$. A similar argument implies that projecting $\{x_i : x_i > R\}$ to R will further reduce $\|(I - J)x\|^2$. Therefore projecting x to X , i.e., projecting to $[-R, \infty)^m$ and then $(-\infty, R]^m$, reduces $\|(I - J)x\|^2$. \square

Appendix B. Proof of Lemma 3.2.

Proof. First, we note that

$$(23) \quad \sum_{s=0}^{t-1} \alpha(s) \lambda^{t-1-s} = \alpha(0) \lambda^{t-1} + \alpha(1) \lambda^{t-2} + \sum_{s=2}^{t-1} \alpha(s) \lambda^{t-1-s},$$

which means that the rate is upper bounded by the last sum on the right side above since the first two tend to 0 at a linear rate $\lambda \in (0, 1)$.

Note that for all $w \in [s-1, s]$ we have $\frac{1}{\sqrt{s}} \leq \frac{1}{\sqrt{w}}$ and $\lambda^{-s} \leq \lambda^{-(w+1)}$ since $\lambda \in (0, 1)$, and therefore

$$(24) \quad \alpha(s)\lambda^{t-1-s} = \frac{\lambda^{t-1-s}}{c_1 + c_2\sqrt{s}} \leq \frac{\lambda^{t-1}\lambda^{-s}}{c_2\sqrt{s}} \leq \frac{\lambda^{t-1}\lambda^{-(w+1)}}{c_2\sqrt{w}} = \frac{\lambda^{t-2-w}}{c_2\sqrt{w}}.$$

This inequality allows us to bound the last term on the right-hand side of (23) by

$$(25) \quad \sum_{s=2}^{t-1} \alpha(s)\lambda^{t-1-s} \leq \sum_{s=2}^{t-1} \int_{s-1}^s \frac{\lambda^{t-2-w}}{c_2\sqrt{w}} dw = \int_1^{t-1} \frac{\lambda^{t-2-w}}{c_2\sqrt{w}} dw = \frac{2\lambda^{t-2}}{c_2} I_t,$$

where I_t is defined by

$$(26) \quad I_t := \frac{1}{2} \int_1^{t-1} \frac{\lambda^{-w}}{\sqrt{w}} dw.$$

By changing of variable $w = u^2$, we obtain $I_t = \int_1^{\sqrt{t-1}} \lambda^{-u^2} du$. Now we have that

$$(27) \quad \begin{aligned} I_t^2 &= \int_1^{\sqrt{t-1}} \int_1^{\sqrt{t-1}} \lambda^{-(u^2+v^2)} dudv = \int_1^{\sqrt{t-1}} \int_1^{\sqrt{t-1}} e^{-(u^2+v^2)\log \lambda} dudv \\ &\leq \int_0^{\sqrt{t}} \int_0^{\sqrt{t}} e^{-(u^2+v^2)\log \lambda} dudv = 2 \int_0^{\pi/4} \int_0^{\sqrt{t}/\cos \theta} e^{-\rho^2 \log \lambda} \rho d\rho d\theta \\ &= -\frac{1}{\log \lambda} \int_0^{\pi/4} (e^{-t \log \lambda / \cos^2(\theta)} - 1) d\theta < -\frac{1}{\log \lambda} \int_0^{\pi/4} e^{-t \log \lambda / \cos^2(\theta)} d\theta, \end{aligned}$$

where the third equality comes from changing to a polar system with the substitutions $u = \rho \cos \theta$ and $v = \rho \sin \theta$. Note that $\cos^{-2}(\theta) - (1 + 4\theta/\pi) \leq 0$ for all $\theta \in [0, \pi/4]$ since $\cos^{-2}(\theta) - 1 - 4\theta/\pi$ is convex with respect to θ and vanishes at $\theta = 0$ and $\theta = \pi/4$. Therefore

$$(28) \quad I_t^2 \leq -\frac{1}{\log \lambda} \int_0^{\pi/4} e^{-t \log \lambda (1+4\theta/\pi)} d\theta \leq \frac{\pi \lambda^{-2t}}{4t(\log \lambda)^2}.$$

Hence, the sum in (25) is bounded by

$$(29) \quad \sum_{s=2}^{t-1} \alpha(s)\lambda^{t-1-s} \leq \frac{2\lambda^{t-2}}{c_2} I_t \leq \frac{2\lambda^{t-2}}{c_2} \frac{\sqrt{\pi}\lambda^{-t}}{2\sqrt{t}\log(\lambda^{-1})} = \frac{\sqrt{\pi}\lambda^{-2}}{c_2\sqrt{t}\log(\lambda^{-1})},$$

which completes the proof. \square

Appendix C. Proof of Corollary 3.4.

Proof. According to the update (4) or equivalently (3), we have

$$(30) \quad \begin{aligned} \mathbb{E}[\|x(t+1) - x(t)\|] &= \mathbb{E}[\|\Pi_{\mathcal{X}}[Wx(t) - \alpha(t)g(t - \tau(t))] - x(t)\|] \\ &\leq \mathbb{E}[\|(I - W)x(t) + \alpha(t)g(t - \tau(t))\|] \\ &\leq \mathbb{E}[\|(I - W)x(t)\|] + \alpha(t) \mathbb{E}[\|g(t - \tau(t))\|], \end{aligned}$$

where we used the facts that $x(t) \in \mathcal{X}$ and that projection $\Pi_{\mathcal{X}}$ is nonexpansive in the first inequality. Note that $WJ = J$ and hence $I - W = (I - W)(I - J)$, we have

$$\mathbb{E}[\|(I - W)x(t)\|] = \mathbb{E}[\|(I - W)(I - J)x(t)\|] \leq \mathbb{E}[\|(I - J)x(t)\|] \leq \frac{\sqrt{\pi m} G \lambda^{-2}}{\eta \sqrt{t} \log(\lambda^{-1})},$$

where we used the fact that $\|I - W\| \leq 1$ in the first inequality and applied Theorem 3.3 to obtain the second inequality.

Furthermore, we have by the definition of $\alpha(t)$ that

$$(31) \quad \|\alpha(t)g(t - \tau(t))\| \leq \sqrt{m}\alpha(t)G = \frac{\sqrt{m}G}{2(L + \eta\sqrt{t})} \leq \frac{\sqrt{m}G}{2\eta\sqrt{t}}.$$

Applying the two inequalities above to (30) yields (12). \square

Appendix D. Proof of Corollary 3.5.

Proof. We first define $\bar{\tau}(t) := \max\{\tau_i(t) : 1 \leq i \leq m\}$. Then there is $\mathbb{E}[|\bar{\tau}(t)|^2] \leq \mathbb{E}[\sum_{i=1}^m |\tau_i(t)|^2] \leq mB^2$. Without loss of generality, we assume that $0 \leq \bar{\tau}(t) \leq t-2$ for every given t ; i.e., we consider the convergence rate when every node has successfully computed their own gradient at least twice. Then we obtain that

$$(32) \quad \begin{aligned} & \mathbb{E}[\|x(t) - x(t - \tau(t))\|] \\ & \leq \mathbb{E} \left[\sum_{s=1}^{\bar{\tau}(t)} \|x(t - s + 1) - x(t - s)\| \right] \leq C \mathbb{E} \left[\sum_{s=1}^{\bar{\tau}(t)} \frac{1}{\sqrt{t-s}} \right] \\ & = C \mathbb{E} \left[\sum_{s=t-\bar{\tau}(t)}^{t-1} \frac{1}{\sqrt{s}} \right] \leq C \mathbb{E} \left[\int_{t-\bar{\tau}(t)-1}^{t-1} \frac{1}{\sqrt{s}} ds \right] \\ & = 2C \mathbb{E} \left[\sqrt{t-1} - \sqrt{t-\bar{\tau}(t)-1} \right] \leq 2C \mathbb{E} \left[\frac{\bar{\tau}(t)}{\sqrt{t-1} + \sqrt{t-\bar{\tau}(t)-1}} \right] \\ & \leq C \mathbb{E} \left[\frac{\bar{\tau}(t)}{\sqrt{t-\bar{\tau}(t)-1}} \right], \end{aligned}$$

where we used triangle inequality to obtain the first inequality, applied Corollary 3.4 to obtain the second inequality, and used the fact that $\bar{\tau}(t) \geq 0$ to obtain the last inequality above. Note that there is

$$(33) \quad \begin{aligned} \mathbb{E} \left[\frac{\bar{\tau}(t)}{\sqrt{t-\bar{\tau}(t)-1}} \right] &= \sum_{s=0}^{\lfloor t/2 \rfloor - 1} \frac{s}{\sqrt{t-s-1}} \mathbb{P}(\bar{\tau}(t) = s) + \sum_{s=\lfloor t/2 \rfloor}^{t-2} \frac{s}{\sqrt{t-s-1}} \mathbb{P}(\bar{\tau}(t) = s) \\ &\leq \frac{\sqrt{2}}{\sqrt{t}} \sum_{s < t/2} s \mathbb{P}(\bar{\tau}(t) = s) + (t-2) \sum_{s \geq t/2} \mathbb{P}(\bar{\tau}(t) = s) \\ &\leq \frac{\sqrt{2m}B}{\sqrt{t}} + \frac{4mB^2(t-2)}{t^2} \leq \frac{\sqrt{2m}B}{\sqrt{t}} + \frac{4mB^2}{t} = O\left(\frac{1}{\sqrt{t}}\right), \end{aligned}$$

where we used the fact that $\sqrt{t-s-1} \geq \sqrt{t/2}$ if $0 \leq s \leq \lfloor t/2 \rfloor - 1$ and $s/\sqrt{t-s-1} \leq t-2$ if $\lfloor t/2 \rfloor \leq s \leq t-2$ to obtain the first inequality, and $\sum_{s < t/2} s \mathbb{P}(\bar{\tau}(t) = s) \leq \mathbb{E}[\bar{\tau}(t)] \leq \sqrt{\mathbb{E}[\bar{\tau}(t)^2]} = \sqrt{m}B$ and $\sum_{s \geq t/2} \mathbb{P}(\bar{\tau}(t) = s) = \mathbb{P}(\bar{\tau}(t) \geq t/2) \leq (4/t^2) \mathbb{E}[\bar{\tau}(t)^2] \leq 4mB^2/t^2$ (by Chebyshev's inequality) in the second inequality. In particular, it is easy to verify that, when $t \geq 8mB^2$, there is $\sqrt{2m}B/\sqrt{t} \geq 4mB^2/t$ and hence $\mathbb{E}[\frac{\bar{\tau}(t)}{\sqrt{t-\bar{\tau}(t)-1}}] \leq \frac{2\sqrt{2m}B}{\sqrt{t}}$. Combining (32) and (33) completes the proof. \square

Appendix E. Proof of Lemma 3.6.

Proof. By the Cauchy–Schwarz inequality, we have that

$$\begin{aligned} & \sum_{t=1}^T \langle \nabla f(x(t)) - \nabla f(x(t - \tau(t))), x(t+1) - x^* \rangle \\ & \leq \sum_{t=1}^T \|\nabla f(x(t)) - \nabla f(x(t - \tau(t)))\| \|x(t+1) - x^*\|. \end{aligned}$$

Note that $\|x(t+1) - x^*\|^2 = \sum_{i=1}^m \|x_i(t+1) - x^*\|^2 \leq mn(2R)^2$ due to the bound of $X = \{x \in \mathbb{R}^n : \|x\|_\infty \leq R\}$, and $\|\nabla f(x(t)) - \nabla f(x(t - \tau(t)))\|^2 = \sum_{i=1}^m \|\nabla f_i(x_i(t)) - \nabla f_i(x_i(t - \tau(t)))\|^2 \leq \sum_{i=1}^m L_i \|x_i(t) - x_i(t - \tau(t))\|^2 \leq L \|x(t) - x(t - \tau(t))\|^2 \leq 2\sqrt{2m}CB/\sqrt{t}$ due to Corollary 3.5. Therefore we obtain

$$\sum_{t=1}^T \langle \nabla f(x(t)) - \nabla f(x(t - \tau(t))), x(t+1) - x^* \rangle \leq 8\sqrt{2nLT}mRCB$$

by using the fact that $\sum_{t=1}^T 1/\sqrt{t} \leq 2\sqrt{T}$. This completes the proof. \square

Appendix F. Proof of Theorem 3.7.

Proof. We first note that there is

$$\begin{aligned} (34) \quad f(x(t+1)) - f(x^*) &= \sum_{i=1}^m (f_i(x_i(t+1)) - f_i(x^*)) \\ &= \sum_{i=1}^m [f_i(x_i(t+1)) - f_i(x_i(t)) + f_i(x_i(t)) - f_i(x^*)] \\ &\leq \sum_{i=1}^m \left[\langle \nabla f_i(x_i(t)), x_i(t+1) - x_i(t) \rangle + \frac{L_i}{2} \|x_i(t+1) - x_i(t)\|^2 \right. \\ &\quad \left. + \langle \nabla f_i(x_i(t)), x_i(t) - x^* \rangle \right] \\ &\leq \sum_{i=1}^m \left[\langle \nabla f_i(x_i(t)), x_i(t+1) - x^* \rangle + \frac{L_i}{2} \|x_i(t+1) - x_i(t)\|^2 \right] \\ &\leq \langle \nabla f(x(t)), x(t+1) - x^* \rangle + \frac{L}{2} \|x(t+1) - x(t)\|^2 \\ &\leq \langle g(t - \tau(t)), x(t+1) - x^* \rangle + \langle \nabla f(x(t)) - g(t - \tau(t)), x(t+1) - x^* \rangle \\ &\quad + \frac{L}{2} \|x(t+1) - x(t)\|^2, \end{aligned}$$

where we used the L_i -Lipschitz continuity of ∇f_i and convexity of f_i to obtain the first inequality. Note that $x(t+1)$ is obtained by (4) as

$$\begin{aligned} (35) \quad x(t+1) &= \operatorname{argmin}_{x \in \mathcal{X}} \left\{ \langle g(t - \tau(t)), x \rangle + \frac{1}{2\alpha(t)} \|x - Wx(t)\|^2 \right\} \\ &= \operatorname{argmin}_{x \in \mathcal{X}} \left\{ \left\langle g(t - \tau(t)) + \frac{1}{\alpha(t)} (I - W)x(t), x \right\rangle + \frac{1}{2\alpha(t)} \|x - x(t)\|^2 \right\}. \end{aligned}$$

Therefore the optimality of $x(t+1)$ in (4) and strong convexity of the objective function in (4) imply that

$$\begin{aligned}
(36) \quad & \langle g(t - \tau(t)), x(t+1) - x^* \rangle \\
& \leq -\frac{1}{\alpha(t)} \langle (I - W)x(t), x(t+1) - x^* \rangle \\
& \quad + \frac{1}{2\alpha(t)} [\|x^* - x(t)\|^2 - \|x(t+1) - x(t)\|^2 - \|x^* - x(t+1)\|^2].
\end{aligned}$$

Furthermore, we note that $\mathbf{1} \in \text{Null}(I - W)$ and x^* is consensual; hence we have

$$\begin{aligned}
(37) \quad & -\frac{1}{\alpha(t)} \langle (I - W)x(t), x(t+1) - x^* \rangle \\
& = -\frac{1}{\alpha(t)} \langle (I - W)(x(t) - x^*), x(t+1) - x^* \rangle \\
& = \frac{1}{2\alpha(t)} (\|x(t) - x(t+1)\|_{I-W}^2 - \|x(t) - x^*\|_{I-W}^2 - \|x(t+1) - x^*\|_{I-W}^2) \\
& \leq \frac{1}{4\alpha(t)} \|x(t) - x(t+1)\|_{I-W}^2,
\end{aligned}$$

where we have used the fact that

$$\|x(t) - x(t+1)\|_{I-W}^2 \leq 2(\|x(t) - x^*\|_{I-W}^2 + \|x(t+1) - x^*\|_{I-W}^2)$$

to obtain the inequality above. We also have that

$$\|x(t) - x(t+1)\|_{I-W}^2 \leq \|x(t) - x(t+1)\|^2$$

with which we can further bound (37) as

$$-\frac{1}{\alpha(t)} \langle (I - W)x(t), x(t+1) - x^* \rangle \leq \frac{1}{4\alpha(t)} \|x(t) - x(t+1)\|^2.$$

Now applying the above inequality and (36) to (34), and taking sum of t from 1 to T , we get

$$\begin{aligned}
(38) \quad & \sum_{t=1}^T f(x(t+1)) - Tf(x^*) \leq \sum_{t=1}^T \frac{1}{2\alpha(t)} (\|x(t) - x^*\|^2 - \|x(t+1) - x^*\|^2) \\
& \quad + \sum_{t=1}^T \left(\frac{L}{2} - \frac{1}{4\alpha(t)} \right) \|x(t) - x(t+1)\|^2 \\
& \quad + \sum_{t=1}^T \langle \nabla f(x(t)) - g(t - \tau(t)), x(t+1) - x^* \rangle.
\end{aligned}$$

Note that the running average $y(T) = (1/T) \sum_{t=1}^T x(t+1)$ satisfies $f(y(T)) \leq (1/T) \sum_{t=1}^T f(x(t+1))$ due to the convexity of all f_i . Therefore together with (38) and the definition of $\alpha(t)$, we have

$$\begin{aligned}
(39) \quad & T[f(y(T)) - f(x^*)] \\
& \leq \sum_{t=1}^T \left[\frac{1}{2\alpha(t)} (\|x(t) - x^*\|^2 - \|x(t+1) - x^*\|^2) - \frac{\eta\sqrt{t}}{2} \|x(t) - x(t+1)\|^2 \right] \\
& \quad + \sum_{t=1}^T \langle \nabla f(x(t)) - g(x(t - \tau(t))), x(t+1) - x^* \rangle.
\end{aligned}$$

Now, by taking expectation on both sides of (39), we obtain

$$\begin{aligned}
 T \mathbb{E}[f(y(T)) - f(x^*)] &\leq \sum_{t=1}^T \left[\frac{1}{2\alpha(t)} (e(t) - e(t+1)) - \frac{\eta\sqrt{t}}{2} \mathbb{E}[\|x(t) - x(t+1)\|^2] \right] \\
 (40) \quad &+ 8\sqrt{2nLT}mRCB \\
 &+ \sum_{t=1}^T \mathbb{E} \langle \nabla f(x(t - \tau(t))) - g(t - \tau(t)), x(t+1) - x^* \rangle,
 \end{aligned}$$

where we denoted $e(t) := \mathbb{E}[\|x(t) - x^*\|^2]$ for notation simplicity.

Now we work on the last sum of inner products on the right side of (40). First we observe that

$$\begin{aligned}
 &\mathbb{E} \langle \nabla f(x(t - \tau(t))) - g(t - \tau(t)), x(t+1) - x^* \rangle \\
 (41) \quad &= \mathbb{E} \langle \nabla f(x(t - \tau(t))) - g(t - \tau(t)), x(t - \tau(t)) - x^* \rangle \\
 &+ \mathbb{E} \langle \nabla f(x(t - \tau(t))) - g(t - \tau(t)), x(t+1) - x(t - \tau(t)) \rangle.
 \end{aligned}$$

Note that $g_i(t - \tau_i(t))$ is the stochastic gradient of node i evaluated at iteration $t - \tau_i(t)$, and the stochastic error $g_i(t - \tau_i(t)) - \nabla f_i(x_i(t - \tau_i(t)))$ is independent of $x_i(t - \tau_i(t))$. Therefore we have

$$\begin{aligned}
 (42) \quad &\mathbb{E} \langle \nabla f(x(t - \tau(t))) - g(t - \tau(t)), x(t - \tau(t)) - x^* \rangle \\
 &= \sum_{i=1}^m \mathbb{E} \langle \nabla f_i(x_i(t - \tau_i(t))) - g_i(t - \tau_i(t)), x_i(t - \tau_i(t)) - x^* \rangle = 0,
 \end{aligned}$$

since the stochastic gradients are unbiased. Furthermore, by Young's inequality, we have

$$\begin{aligned}
 &\mathbb{E} \langle \nabla f(x(t - \tau(t))) - g(t - \tau(t)), x(t+1) - x(t - \tau(t)) \rangle \\
 (43) \quad &\leq \frac{2}{\eta\sqrt{t}} \mathbb{E}[\|\nabla f(x(t - \tau(t))) - g(t - \tau(t))\|^2] + \frac{\eta\sqrt{t}}{2} \mathbb{E}[\|x(t+1) - x(t)\|^2] \\
 &\leq \frac{2m\sigma^2}{\eta\sqrt{t}} + \frac{\eta\sqrt{t}}{2} \mathbb{E}[\|x(t+1) - x(t)\|^2],
 \end{aligned}$$

where we used the fact that $\mathbb{E}[\|\nabla f(x(t - \tau(t))) - g(t - \tau(t))\|^2] \leq m\sigma^2$ for all t . Now applying (41), (42), and (43) in (40), we have

$$\begin{aligned}
 T \mathbb{E}[f(y(T)) - f(x^*)] &\leq \sum_{t=1}^T \frac{1}{2\alpha(t)} (e(t) - e(t+1)) + 8\sqrt{2nLT}mRCB + \sum_{t=1}^T \frac{2m\sigma^2}{\eta\sqrt{t}} \\
 (44) \quad &\leq \frac{e(1)}{2\alpha(1)} + \sum_{t=2}^T \frac{e(t)}{2} \left(\frac{1}{\alpha(t)} - \frac{1}{\alpha(t-1)} \right) + 8\sqrt{2nLT}mRCB + \sum_{t=1}^T \frac{2m\sigma^2}{\eta\sqrt{t}},
 \end{aligned}$$

where we note that $\alpha(t)$ is nonincreasing, and hence $\frac{1}{\alpha(t)} - \frac{1}{\alpha(t-1)} \geq 0$ and

$$\sum_{t=2}^T \frac{e(t)}{2} \left(\frac{1}{\alpha(t)} - \frac{1}{\alpha(t-1)} \right) \leq \frac{\mathcal{D}_{\mathcal{X}}^2}{2} \sum_{t=2}^T \left(\frac{1}{\alpha(t)} - \frac{1}{\alpha(t-1)} \right) = \frac{\mathcal{D}_{\mathcal{X}}^2}{2} \left(\frac{1}{\alpha(T)} - \frac{1}{\alpha(1)} \right),$$

where we used the fact that $e(t) = \mathbb{E}[\|x(t) - x^*\|^2] \leq \mathcal{D}_{\mathcal{X}}^2 := 4mnR^2$ for all t . Plugging this into (44), dividing both sides by T , and using the fact that $\sum_{t=1}^T 1/\sqrt{t} \leq 2\sqrt{T}$, we obtain (15). This completes the proof. \square

Acknowledgments. We would like to thank the associate editor and the anonymous reviewers for their valuable comments, which helped us to significantly improve the presentation of this paper. The authors would also like to thank Dr. WenZhan Song and his SensorWeb Research Laboratory at University of Georgia for sharing the illustrative Figure 3 and the three test seismic tomography datasets in this paper.
